Comparative investigations of the crystal structure and photoluminescence property of eulytite-type \( \text{Ba}_3\text{Eu(PO}_4)_3 \) and \( \text{Sr}_3\text{Eu(PO}_4)_3 \)

Haipeng Ji,a Zhaohui Huang,\!*\!a Zhiguo Xia,*b Maxim S. Molokeev,c,d Xingxing Jiang,e,f Zheshuai Lin*e and Victor V. Atuching,h,i

In this study, the \( \text{Ba}_3\text{Eu(PO}_4)_3 \) and \( \text{Sr}_3\text{Eu(PO}_4)_3 \) compounds were synthesized and the crystal structures were determined for the first time by Rietveld refinement using powder X-ray diffraction (XRD) patterns. \( \text{Ba}_3\text{Eu(PO}_4)_3 \) crystallizes in cubic space group \( \text{I}a\text{3d} \), with cell parameters of \( a = 10.47996(9) \ \text{Å} \), \( V = 1151.01(3) \ \text{Å}^3 \) and \( Z = 4 \). \( \text{Ba}^{2+} \) and \( \text{Eu}^{3+} \) occupy the same site with partial occupancies of \( 3/4 \) and \( 1/4 \), respectively. Besides, in this structure, there exists two distorted kinds of the PO4 polyhedra orientation. \( \text{Sr}_3\text{Eu(PO}_4)_3 \) is isomorphous to \( \text{Ba}_3\text{Eu(PO}_4)_3 \) and has much smaller cell parameters of \( a = 10.1203(2) \ \text{Å} \), \( V = 1036.52(5) \ \text{Å}^3 \). The bandgaps of \( \text{Ba}_3\text{Eu(PO}_4)_3 \) and \( \text{Sr}_3\text{Eu(PO}_4)_3 \) are determined to be 4.091 eV and 3.987 eV, respectively, based on the UV–Vis diffuse reflectance spectra. The photoluminescence measurements reveal that, upon 396 nm \( n \)-UV light excitation, \( \text{Ba}_3\text{Eu(PO}_4)_3 \) and \( \text{Sr}_3\text{Eu(PO}_4)_3 \) exhibit orange-red emission with two main peaks at 596 nm and prevailing 613 nm, corresponding to the \( ^5\text{D}_0 \rightarrow ^7\text{F}_1 \) and \( ^5\text{D}_0 \rightarrow ^7\text{F}_2 \) transitions of \( \text{Eu}^{3+} \), respectively. The dynamic disordering in the crystal structures contributes to the broadening of the luminescence spectra.

The electronic structure of the phosphates was calculated by the first-principles method. The analysis elucidates that the bond structures are mainly governed by the orbits of phosphorus, oxygen and europium, and the sharp peaks of the europium f-orbit occur at the top of the valence bands.

1. Introduction

Recently, the rare-earth eulytite-type phosphates \( \text{A}_3\text{Ln(PO}_4)_3 \) (\( \text{A} = \text{Ca, Sr, Ba, Pb; Ln} \rightarrow \text{Lu, Bi, Y, Sc, In} \)) and related phosphors formed by doping with rare-earth ions have attracted interest due to their specific spectroscopic properties. Initially, the eulytite-type structure was recognized in the mineral \( \text{Bi}_4(\text{SiO}_4)_3 \), featuring irregular \( \text{BiO}_6 \) polyhedra and \( \text{SiO}_4 \) tetrahedra. Then, with the substitution of P for Si and the charge balancing \( (3\text{A}^{2+} + \text{Ln}^{3+}) \) for \( 4\text{Bi} \), the formation of the artificial eulytite-type phosphates with a general formula \( \text{A}_3\text{Ln(PO}_4)_3 \) is reasonably supposed and the compounds represent an important phase family in the \( \text{AO}-\text{Ln}_2\text{O}_3-\text{P}_2\text{O}_5 \) ternary systems.

Owing to the chemical stability and mild synthesis conditions, \( \text{A}_3\text{Ln(PO}_4)_3 \) are targeted as hosts for various luminescent ions in fabricating phosphors for applications in white light emitting diodes (w-LEDs). Hoogendorp et al.\!*\! have prepared and evaluated the luminescence properties of \( \text{(Ba,Sr)}_3\text{La(PO}_4)_3;\text{Ce}^{3+} \) phosphors. Xia et al.\!*\! reported the efficient color hue tuning of \( \text{(Ba,Str)}_3\text{Lu(PO}_4)_3;\text{Eu}^{3+} \) phosphors by cation substitution. Kuo et al.\!*\! and Wang et al.\!*\! prepared the \( \text{Ce}^{3+}/\text{Tb}^{3+} \) and \( \text{Ce}^{3+}/\text{Mn}^{2+} \) co-doped \( \text{Sr}_3\text{La(PO}_4)_3 \) green- and orange-red-emitting phosphors. Zhang et al.\!*\! prepared \( \text{Eu}^{3+}/\text{Tb}^{3+} \) co-doped \( \text{Ba}_3\text{La(PO}_4)_3 \) and observed that \( \text{Tb}^{3+} \) can efficiently transfer the excitation energy to \( \text{Eu}^{3+} \) and sensitize the \( \text{Eu}^{3+} \) emission. Hou et al.\!*\! prepared \( \text{Ba}_3\text{Gd(PO}_4)_3;\text{Eu}^{3+} \) phosphor and studied the energy transfer from \( \text{Gd}^{3+} \) to the \( \text{Tb}^{3+} \) dopant ions. You’s group found that warm white light emission

†Electronic supplementary information (ESI) available: CIF files giving crystallographic data for \( \text{Ba}_3\text{Eu(PO}_4)_3 \) and \( \text{Sr}_3\text{Eu(PO}_4)_3 \). See DOI: 10.1039/c4dt03887h
can be directly obtained from various Eu\textsuperscript{2+}/Mn\textsuperscript{2+} co-doped euylite-type phosphates such as Sr\textsubscript{5}Y(PO\textsubscript{4})\textsubscript{3}\textsuperscript{13}, Sr\textsubscript{5}Sc(PO\textsubscript{4})\textsubscript{3}\textsuperscript{3}, Ba\textsubscript{3}Lu(PO\textsubscript{4})\textsubscript{3}\textsuperscript{6} and Ba\textsubscript{3}Gd(PO\textsubscript{4})\textsubscript{3}\textsuperscript{11}. They further reported that tunable emission can be realized by the efficient energy transfer between the dopant ion Mn\textsuperscript{2+} and the structural ion Tb\textsuperscript{3+} in Sr\textsubscript{5}Tb(PO\textsubscript{4})\textsubscript{3}:Mn\textsuperscript{2+}.\textsuperscript{12} Bettinelli et al.\textsuperscript{13,14} investigated the energy transfer in the Tb\textsuperscript{3+} → Eu\textsuperscript{3+} pair in Sr\textsubscript{5}Tb\textsubscript{0.90}Eu\textsubscript{0.10}(PO\textsubscript{4})\textsubscript{3}, where the transfer efficiency can be as high as 0.93 and the quantum yield is promising for lighting technology. These interesting results inspire us to prepare hosts with luminescent ion and utilize energy transfer to the dopant to achieve emission color tuning.

The Eu\textsuperscript{3+} is one luminescent ion characterized by orange-red line-type emission from the 4f-4f transition, and Eu\textsuperscript{3+}-doped phosphors commonly act as a red-emitting component in w-LEDs.\textsuperscript{15,16} A\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} (A = Ba, Sr, Ca) belong to eulytite-type phosphates commonly act as a red-emitting component for other dopants (such as Sm\textsuperscript{3+} or Tb\textsuperscript{3+}). In this study, we synthesized Ba\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} and Sr\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3}, firstly determined their crystal structures by Rietveld refinement, and characterized the physical properties concerning the photoluminescence spectra, diffuse reflectance spectra, bandgap as well as the electronic structure. Close attention was also paid to the exploration of the structural disorder influence on the crystallization and the Eu\textsuperscript{3+} photoluminescence in eulytite phosphates.

2. Experimental and data processing

The high-temperature solid state reaction method conventionally used for eulytite phosphate preparation was employed to crystallize Ba\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} and Sr\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3}. The stoichiometric mixtures of BaCO\textsubscript{3}/SrCO\textsubscript{3} (Analytical Reagent, A. R.), Eu\textsubscript{2}O\textsubscript{3} (99.99%), NH\textsubscript{4}H\textsubscript{2}PO\textsubscript{4} (A. R.) were calcined at 800 °C for 4 h to decompose the carbonate and ammonium phosphates, and then were sintered at 1250 °C for 10 h in the air in a tube furnace. After maintaining at the highest temperature, the furnace was shut down and the samples were slowly cooled together with the furnace. After synthesis, the samples were reground into fine powders.

The X-ray diffraction (XRD) data of the powder samples were collected on an X-ray powder diffractometer (D/max-IIIA, Rigaku, Japan) with a step-wise scanning mode over the 2θ range of 5–120°, using Cu Kα radiation (1.5406 Å) under the operating electric voltage and current of 40 kV and 100 mA, respectively. The acquisition of the XRD patterns, which were submitted to Rietveld refinement, was in the step size of 0.02° and counting time of 3 s per step. The photoluminescence spectra were recorded on a fluorescence spectrophotometer (F-4600, Hitachi, Japan) with a photomultiplier tube operating at 500 V using a 150 W Xe lamp as the excitation source. The diffuse reflection spectra were measured on an UV–Vis–NIR spectrophotometer (UV–3700, Shimadzu, Japan) attached with an integrating sphere. Pure BaSO\textsubscript{4} powder was used as a reference for 100% reflectance.

3. Results and discussion

3.1. Phase formation and structural characteristics

The powder XRD patterns of Ba\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} and Sr\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} were collected by the way described above. Previously, their patterns were indexed (PDF no. 29-0162 and 48-0410), but the crystal structures remained unsolved. We therefore performed Rietveld refinements of the two patterns using TOPAS 4.2.\textsuperscript{23} Fig. 1 presents the observed (red), calculated (black), and difference (gray) XRD profiles for Ba\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} and Sr\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3}, as refined by Rietveld method. It is found that all peaks in the patterns can be indexed by a cubic cell (I\textsuperscript{4}3d) with parameters close to those of Ba\textsubscript{3}La(PO\textsubscript{4})\textsubscript{3},\textsuperscript{24} which is also in the eulytite-type structure. The pattern of Sr\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} sample contains a small amount of impurity peaks, the intensities and positions of which can be fitted by the monoclinic Sr\textsubscript{9}In(PO\textsubscript{4})\textsubscript{7} (PDF 53-179). The In\textsuperscript{3+} ion has ionic radii similar to that of Eu\textsuperscript{3+}. Thus, it is concluded that the impurity is the Sr\textsubscript{9}Eu(PO\textsubscript{4})\textsubscript{7} compound. The structure of Ba\textsubscript{3}La(PO\textsubscript{4})\textsubscript{3} was taken as the starting model for the main phase and was used for Rietveld refinement of Ba\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} and Sr\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3}. The site of Ba(Sr) (16c site of the I\textsuperscript{4}3d space group) was assumed to be occupied by the Ba(Sr) ion at fixed occupation P = 3/4 and by Eu ion at P = 1/4. With this assumption, the sum of occupancies of all ions in this site is equal to 1.00. Thus, Ba/ Eu (Sr/Eu) ions locate in one site and are randomly distributed over the Ba\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} and Sr\textsubscript{3}Eu(PO\textsubscript{4})\textsubscript{3} crystals. In the crystals, there is one more disordering process in the oxygen sublattice. In the Ba\textsubscript{3}La(PO\textsubscript{4})\textsubscript{3}
The PO4 tetrahedron is disordered over two positions with probability 0.65/0.35, that is governed by the bonding requirements of the metal atoms. Our structural model accounts for this and generates two different oxygen sites O1 and O2 corresponding to two different orientations of PO4 tetrahedrons. The occupancy of O1 ion is equal to x and the occupancy of O2 ion is equal to (1 − x). The value of x took the starting value 0.65 and was then refined. The refinement was stable and ended with relatively low R-factors. Fig. 2 depicts the refined crystal structures by VESTA, in which the two different orientations of PO4 tetrahedrons are diversely colored. The Eu3+ ions are isolated by the surrounding PO4 groups. The final structural parameters together with the details of the refinement are listed in Table 1. The crystallographic information file (CIF) of Ba3Eu(PO4)3 and Sr3Eu(PO4)3 are given in the ESI.†

Besides, the synthesis of sample with nominal composition of Ca3Eu(PO4)3 was also performed using the same procedure as described in the Experimental section. The result, however, was a failure giving the phase mixture of Ca3(PO4)2 and EuPO4. In comparison, we noticed that, if Eu3+ in the Ln site of A3Ln(PO4)3 is completely substituted by La3+, it is possible to crystallize a series of isostructural Ba3La(PO4)3, Sr3La(PO4)3 and Ca3La(PO4)3. Actually, the preparation of Ca3Eu(PO4)3 has been reported by firing at 1400 °C for 4 days followed by air quenching, which is practically stringent. In the present case of A3Eu(PO4)3, when Ba2+ is fully substituted by Sr2+, the cell volume considerably decreases from 1151.01(3) to 1036.52(5) Å3, while the cell volume of Ca3Eu(PO4)3 was reported to be 960.63 Å3. Thus, it is assumed that the ion radius ratio of A2+/Ln3+ dominates the phase formation ability of pure A3Ln(PO4)3, and the Ca2+ with the effective radius of 1.18 Å (CN = 9) fails to fulfill the ratio requirement. Here, we would like to further summarize the reports on the eulytite phosphate A3Ln(PO4)3 structures, where A site is Ba, Sr, or Ca.
and Ln site is Bi, Y, La, Lu, Sc, Gd, Tb, or Eu, as shown in Table 2. Predominantly, compounds with A = Ba, Sr, Ca can form pure eulytite phases. The A3Ln(PO4)3 (Ln = Lu and Tb) with A = Ba, Sr can form a pure phase; while when A = Ca, the formation of a eulytite structure can be achieved only by developed processing such as quenching. In the eulytite-type structure, the A and Ln ions share the same site and, the crystallization is problematic when smaller Ca2+ and relatively big Ln3+ ions are combined.

Previously, Barbier et al.24 performed refinements of Ca3Bi(PO4)3 and Ba3La(PO4)3 using neutron diffraction data, and found that the oxygen sublattice disorder in the type of rotational disorder of the tetrahedral groups can be expected to occur in all mixed metal eulytites. The reason is intrinsically associated with different metal–oxygen bond lengths and most eulytite phases are thermodynamically stable only at high temperatures. The presence of a heavy metal atom and the lone-pair bonding stabilize the eulytite structure at lower temperature and reduce the structural disorder degree by retaining the oxygen atoms in positions close to those observed in Bi4(SiO4)3. Large metal atoms such as Ba and Sr appear to have a stabilizing effect on the structure, whereas the Ca analog can be purely obtained only by quenching.31

### 3.2. UV–Vis diffuse reflectance spectra and bandgap determination

Bandgap is a basic material property of a compound. For a powder sample, the diffuse reflectance measurement is a convenient technique to evaluate the optical absorption properties. Fig. 3(a) showed the UV–Vis reflectance spectra of Ba3Eu(PO4)3 and Sr3Eu(PO4)3. The Tauc plot based on the Kubelka-Munk function (eqn (1)) is used to estimate the bandgaps:

\[
(h\nu \alpha)^{1/n} = A/(h\nu - E_g)
\]

Here, \( h \) is Planck’s constant, \( \nu \) is frequency of vibration, \( \alpha \) is absorption coefficient, \( E_g \) is bandgap, and \( A \) is a constant. Exponent value \( n \) denotes the nature of electron transition: \( n = 1/2 \) for direct allowed transition and \( n = 2 \) for indirect allowed transition. Using the eqn (1), the \((h\nu\alpha)^{1/n}\) is plotted against the \( h\nu \). A line is drawn tangent to the point of inflection on the curve to determine the bandgap value \( E_g \). Since we do not know the nature of transition in these compounds, both \( n = 1/2 \) and \( 2 \) were examined. From Fig. 3(a), at 310 nm the reflectance drops steeply with respect to wavelength, and the bandgaps can be roughly estimated to be 1240/310 = 4 eV;

*Y indicates that the compound can be purely crystallized; N indicates that the nominal compound cannot be purely crystallized or has not been reported on.
here, the case of $n = 1/2$ generate results closer to the above value. Thus, as shown in Fig. 3(b, c), the bandgaps of $\text{Ba}_3\text{Eu(PO}_4\text{)}_3$ and $\text{Sr}_3\text{Eu(PO}_4\text{)}_3$ were finally determined to be 4.091 eV and 3.987 eV, respectively.

3.3. Photoluminescence spectra analysis

Both of the powder products are of white color under sunlight and emit orange-red light under the 365 nm UV light illumination which suggests similar spectroscopic properties. Thus, the following luminescence investigation is concentrated on one of them, namely $\text{Ba}_3\text{Eu(PO}_4\text{)}_3$. Fig. 4 depicts the photoluminescence emission and excitation spectra at room temperature. Upon the 396 nm excitation, the emission spectrum of $\text{Ba}_3\text{Eu(PO}_4\text{)}_3$ (Fig. 4a) contains the typical transitions of Eu$^{3+}$ from the excited $5\text{D}_0$ energy level to the ground state $7\text{F}_j$ ($j = 0$, 1, 2, 3, 4) multiplets.$^{16,64,65}$ Two main peaks at 613 nm and 596 nm exhibit the relatively high intensity corresponding to the allowed $5\text{D}_0 \rightarrow 7\text{F}_2$ electric-dipole transition (ED) and $5\text{D}_0 \rightarrow 7\text{F}_1$ magnetic-dipole transition (MD), respectively. The ED transition is super sensitive to the Eu$^{3+}$ site symmetry, whereas the MD one is insensitive to that, and this behavior can be used to predict the Eu$^{3+}$ position symmetry. In the considered case, the prevailing peak at 613 nm dominates the emission, suggesting that Eu$^{3+}$ in the crystal occupies a noncentrosymmetric site with low symmetry. Indeed, crystal structure refinement indicates that the Eu and Ba ions share the same site $(x', x', x'') (x'' = 0.0634)$ in $\text{Ba}_3\text{Eu(PO}_4\text{)}_3$, which has a 16c Wyckoff position and site symmetry of “3.” Therefore, only a 3-fold axis goes through this position and there is no inversion center. The observed emission character of Eu$^{3+}$ is in line with structural information from the XRD refinement. Moreover, the emission bands are relatively wide compared with Eu$^{3+}$ emission in other crystalline matrices; herein, the Eu$^{3+}$ ion shares the same crystallographic site with the Ba$^{2+}$ (or Sr$^{2+}$) ion and is coordinated with oxygen occupied in disordered sublattice sites. The specific dynamic disordering in the eulytite-type compounds is believed to induce much more energy level splitting of Eu$^{3+}$, which then causes the broadening of the luminescence emission spectrum of Eu$^{3+}$. The excitation spectrum monitored at 613 nm is shown in Fig. 4b which contains a series of sharp excitation bands between 280 and 420 nm. These sharp bands originate from the intra-configurational 4f–4f transitions in Eu$^{3+}$, namely, $7\text{F}_0$ to $5\text{F}_j$, $5\text{H}_4$, $5\text{H}_3$, $5\text{D}_4$, $5\text{I}_8$, $5\text{G}_3$, $5\text{G}_2$, $5\text{L}_6$, and $5\text{D}_3$ at wavelengths 297, 317, 326, 362, 365, 376, 382, 394, and 413 nm, respectively.$^{48}$ The $\text{Ba}_3\text{Eu(PO}_4\text{)}_3$ luminescence is observed to be similar to that of $\text{Ba}_3\text{La(PO}_4\text{)}_3$: Eu$^{3+}$. The photoluminescence spectra of $\text{Sr}_3\text{Eu(PO}_4\text{)}_3$ (Fig. 4c) is almost similar to that of $\text{Ba}_3\text{Eu(PO}_4\text{)}_3$ because, in both the isostructural phosphates, the luminescence property originates from the Eu$^{3+}$ ion which experiences the same site symmetry.

3.4. Electronic structure analysis

The $\text{Ba}_3\text{Eu(PO}_4\text{)}_3$ and $\text{Sr}_3\text{Eu(PO}_4\text{)}_3$ exhibit similar electronic structures. The partial density of states (PDOS) projected onto the constituent atoms of them are plotted in Fig. 5. Some characteristic features can be accordingly deduced: (1) the PDOS of europium in different spin states split seriously from each other due to the strong spin-related correlation for the f-electrons, while no obvious spin-splitting was observed for other elements; (2) the Ba 5s, Sr 4s,
and Eu 5s orbits are deeply located in the inner energy level below −20 eV, which is difficult to be excited by the external perturbation of the optical electric field, indicating that they almost make no contribution to the optical properties related to the electronic transition across the forbidden band. These orbits hybridize little with each other, verifying that they almost do not participate in the formation of the covalent bonds; (3) the energy states between −20 eV and −9 eV mainly consist of Ba 5p (Sr 4p), Eu 5p, P 3s and O 2s orbits. The strong hybridization between the Eu, P and O orbits in this region indicates the strongly covalent P–O and Eu–O interactions. However, the sharp peaks of Ba 5p (Sr 4p) orbitals occur at −10 eV (−14 eV), proving the strong ionicity of barium (strontium); and (4) the energy levels near the forbidden bands are mainly composed of P 3p, O 3p and Eu 4f orbits. This indicates that the optical property is dominantly determined by the electron transitions within (PO₄)³⁻ groups and the f–f transition of europium. Especially a sharp peak of the Eu 4f orbital of the spin-up electrons occupies the top of the valence bands and contributes a lot to the bottom of the conduction bands, verifying that the electron transition to the ⁵D₀ configuration dominates the photoluminescence properties of Ba₃Eu(PO₄)₃ and Sr₃Eu(PO₄)₃.

4 Conclusions

Ba₃Eu(PO₄)₃ and Sr₃Eu(PO₄)₃ can be successfully synthesized at 1250 °C via the high temperature solid state reaction method followed by furnace-cooling while the Ca₃Eu(PO₄)₃ analog cannot purely crystallize in the same way. The ion radius ratio of A²⁺/Ln³⁺ dominates the phase formation ability of pure A₃Ln(PO₄)₃. Rietveld refinements show that Ba₃Eu(PO₄)₃ and Sr₃Eu(PO₄)₃ are isostructural, both holding the cubic eulytite-type disordered structure in space group I4₃d. Ba₃Eu(PO₄)₃ has cell parameters of a = 10.47996(9) Å, V = 1151.01(3) Å³, Z = 4, while Sr₃Eu(PO₄)₃ has much smaller cell parameters of a = 10.1203(2) Å, V = 1036.52(5) Å³. Based on the diffuse reflectance spectra, the bandgaps of Ba₃Eu(PO₄)₃ and Sr₃Eu(PO₄)₃ are estimated to be about 4.091 eV and 3.987 eV, respectively. Upon 396 nm UV light excitation, Ba₃Eu(PO₄)₃ and Sr₃Eu(PO₄)₃ exhibit orange-red emission with two main peaks at 596 nm and 613 nm, corresponding to the ⁵D₀ → ⁷F₁ and ⁵D₀ → ⁷F₂ transitions of Eu³⁺, respectively. The 613 nm emission dominates the photoluminescence property because the Eu³⁺ ion occupies the 16c Wyckoff position in the crystal which has no inversion center. The electronic structure calculation verifies that the Eu 4f orbital mainly occupies the top of the valence bands and the bottom of the conduction bands, and the electron transition to the ⁵D₀ configuration dominates the photoluminescence properties.
